Abstract—Cryptocurrencies have emerged as a new form of digital money that has not escaped the eyes of cyber-attackers. Traditionally, they have been maliciously used as a medium of exchange for proceeds of crime in the cyber dark-market by cybercriminals. However, cyber-criminals have devised an exploitative technique of directly acquiring cryptocurrencies from benign users’ CPUs without their knowledge through a process called crypto mining. The presence of crypto mining activities in a network is often an indicator of compromise of illegal usage of network resources for crypto mining purposes. Crypto mining has had a financial toll on victims such as corporate networks and individual home users. This paper addresses the detection of crypto mining attacks in a generic network environment using dynamic network characteristics. It tackles an in-depth overview of crypto mining operational details and proposes a semi-supervised machine learning approach to detection using various crypto mining features derived from complex network characteristics. The results demonstrate that the integration of semi-supervised learning with complex network theory modeling is effective at detecting crypto mining activities in a network environment. Such an approach is helpful during security mitigation by network security administrators and law enforcement agencies.

Keywords—bitcoin, cryptocurrency, cyber-attack, crypto mining, semi-supervised learning, complex networks

I. Introduction

The general aim of conventional cyberattacks has generally been to obtain monetary proceeds of the associated cybercrime. Attackers have had the challenge of acquiring these monetary proceeds with little or no monetary trail since conventional payments leave a trail of traceable financial activities [1].Monetary activity trails have enabled law enforcement agencies to track and prosecute cybercriminals. As such, cybercriminals have sought ways to avoid conventional moneraty payment systems. Cryptocurrencies have alleviated this challenge as they provide for privacy and anonymity [2].

The strong privacy provided in cryptocurrencies makes it almost impossible to trace financial payments [3]. As such, cryptocurrencies have become a de facto method of payments in most finance-related cyber-attacks [4], a trend not uncommon in crypto-ransomware attacks.

Victims of recent cybercrimes (such as ransomware attacks) have had to make payments in cryptocurrencies such as Bitcoin. Since these cryptocurrencies are stored on the victim’s computers, attackers have now moved on to attack users of cryptocurrencies in order to extract cryptocurrencies from digital wallets as was evidenced in various attacks [5]. Furthermore, it is not uncommon to find financial malware that seeks to steal cryptocurrencies from targeted users as an extra functionality [6]. Since not all targeted users harbor cryptocurrencies, attackers have devised a technique of directly generating cryptocurrencies from the victims’ CPU (crypto mining) by enlisting them to a mining pool. The cryptocurrencies are generated by installable malware or via browser-based crypto mining. Victims are enlisted in a crypto mining pool since solo mining is not efficient [7]. As such, corporate or enterprise networks are attractive to crypto mining attackers because they provide a pool of devices for crypto mining. It is thus not uncommon to find illegal crypto mining cloud computing and IoT environments [8] as well as critical infrastructure systems such as SCADA [9]. Illegal crypto-mining has since been on the rise and costed victims millions of dollars [10]. Consequently, the year 2018 saw the growth of crypto mining malware by 4,000% [11]. As such, crypto mining attacks have proven to be a force to reckon with which can longer be avoided even as attackers have been eschewing the infamous ransomware attacks [12]. The diagram in Figure 1 shows the decline in ransomware attacks versus the rise in crypto mining attacks according to the IBM-X-Force Threat Intelligence Index 2019 [13].
Crypto mining is taking over ransomware owing to its ease of administration; easily proliferated by phishing emails, no user input required and the difficulty associated with tracing the perpetrators. These advantages have seen an increase in the stealthier attacks, i.e. crypto mining, by 450% even as cybercriminals pivot from the common ransomware attacks [14]. Crypto mining attacks present a million-dollar industry [15].

In Africa, crypto mining is particularly prevalent in Ethiopia, Tanzania, and Zambia which account for 3 of the top-5 countries largely impacted by crypto-mining attacks, according to a Microsoft report [16]. The most impacted victims are SMEs as the security therein is not as robust as in larger corporations.

Like all malware activities and cyberattacks, crypto mining activities generate noise in the form of network traffic. However, the types of network characteristics associated with these types of attacks are peculiar to crypto mining in that victims enlisted to a mining pool or botnet needs to communicate with the associated C2 servers and mining servers. As such, the detection of crypto mining activities in a network environment calls for an approach that takes into consideration these network characteristics. This paper addresses the detection of crypto mining attacks in a generic network environment using dynamic network characteristics. It tackles an in-depth overview of crypto mining operational details and proposes a machine learning approach to detection using various crypto mining features derived from the network characteristics. The Small-World network models [17] of complex network evolution theory are adopted for attack modeling and we use a semi-supervised approach to machine learning for detection.

The rest of the paper is organized as follows; Section II presents the related works while the methodology and proposed detection framework are brought forth in Section III. The results and the analyses thereof of real-world in Section IV and the conclusion is drawn in Section V.

II. Related Works

Even though crypto-mining attacks are a fairly new phenomenon, they have attracted significant attention in the security landscape. Some research works have concentrated on crypto mining in general computer systems [18] whilst others have narrowed the scope to critical infrastructure and IoT [19]. Muhammad et al. [20] propose an end-to-end analysis of browser-based crypto mining by statically and dynamically examining the rise of crypto mining in the real world cases. The proposed approach inspects the traversing traffic between websockets without blacklisting of IP addresses. They achieve a detection accuracy of 96.4% using code analysis.

Zareh and Shahriari [21] propose a host-based approach to crypto mining called BotcoinTrap. Modeling via dynamic analysis of executable binary crypto mining files to detect Bitcoin-mining botnets is adopted. The advantage of this approach is that it can detect Bitcoin mining botnets at the lowest level of execution. The Bitcoin block header is centrally used as the pivotal piece of information in this detection methodology. The drawback of this approach is that it specifically applies only to the detection of Bitcoin miners, whereas the crypto mining landscape has seen the emerging of competing and easy-to-mine cryptocurrencies such a Monero and Ethereum.

Eskandari et al. [22] examine recent trends towards in-browser mining of cryptocurrencies. They concentrate their efforts on the mining of Monero cryptocurrency via CoinHive and those of similar code-bases. In their model, a web user visits a vulnerable site infected with JavaScript code that executes on the client-side browser, thus mining a cryptocurrency without the user's consent. They further survey the crypto mining landscape in order to conduct measurements to establish the prevalence and profitability thereof. They outline the ethical framework for classifying the attack as an inherent attack or business opportunity. They delineate the various stages involved in the process crypto mining process and thereafter brief the various terms associated with crypto mining. However, their approach does not address the systematic detection of crypto mining.

Carlin et al. [23] approach crypto mining detection using dynamic opcode analysis on non-executable files. They use a specified dataset to achieve high detection rates of browser-based crypto mining using Random forest (RF) as the preferred classification algorithm. Their model distinguishes between crypto mining websites, weaponized benign crypto mining websites, de-weaponized crypto mining websites, and real-world benign crypto mining websites. As such, their technique offers an opportunity not only to detect but to prevent as well as mitigate crypto-mining attacks.

Veselý and Žádník [24] present an in-depth analysis of the crypto mining operation. They designed and implemented a passive-active flow monitoring and catalog to detect crypto-mining activities from compromised devices in a network. They tested the feasibility of their approaches to real-life data where passive-active detection is capable of discovering emerging or deliberately hidden crypto mining pools.

Table I summarizes the differences between our proposed model and existing approaches.

As can be seen in Table I, our modeling and detection approach has several advantages not limited to dependency on the prevailing attack vector (i.e. browser-based or installable binary-based) and incorporation of complex network modeling for effective detection.
III. Methodology and Proposed Framework

The enlisting of vulnerable and exploitable devices to a crypto mining pool is a dynamic process that can be viewed as an evolution of node-addition or deletion in an attack graph. Since the nodes in the mining pool interact one with the other and with the central server, the system can thus be characterized by vertex degrees and clustering coefficients. It is on this premise that we employ the use of Small-World network models of complex network theory to depict the behaviour of the attack network and deduce the corresponding features for purposes of detection. The diagram in Figure 2 shows a time-slice crypto-mining depicting the initialization and growth of a crypto mining pool in a target network.

Since the nodes in the mining pool interact one with the other and with the central server, the system can thus be characterized by vertex degrees and clustering coefficients. It is on this premise that we employ the use of Small-World network models of complex network theory to depict the behaviour of the attack network and deduce the corresponding features for purposes of detection. The diagram in Figure 2 shows a time-slice crypto-mining depicting the initialization and growth of a crypto mining pool in a target network.

Equation (1) depicts the dynamic transitions of a victim device enlisted to a mining pool at a point in time as echoed in Figure 2.

As the state of the enlisted victim devices transitions from state $S_0$ to $S_n$, a series of network traffic is generated which we use to derived features for the detection process.

Members enlisted in a crypto mining pool used dedicated protocols to coordinate the distributed mining process. The 3

2 Proof-of-work refers to the cryptographic computational puzzle that miners have to solve in order to be issued a crypto currency unit.
common TCP-based crypto mining protocols are GetWork, GetBlockTemplate, and Stratum protocol [25]. Other traffic details found in crypto mining pools include registration and authentication traffic, recurrent assignment of work packages provided by the crypto mining server. It is from these dynamic traffic details that we draw features to devise a detection methodology. In light of this, we present a semi-supervised learning approach to crypto mining detection that takes advantage of the huge amount of unclassified dataset [26] to perform classification of suspicious hosts participating in crypto mining activities and using few labeled instances from the labeled data. The proposed detection framework is shown in Figure 3.

Our semi-supervised approach shown in Figure 3 shows that in addition to unlabeled raw data (network flow traffic), we have a set of labeled data with features depicted in Table 1. Our semi-supervised approach uses complex network characteristics features of unlabeled data (clustering coefficients and vertex degrees) to create a supervised model. The feature extraction step in the supervised section of our approach uses a mapping scheme to extract hosts from the unlabeled dataset.

We propose a semi-supervised learning approach where we first derive different clusters mainly based on the clustering coefficient and vertex degree. To analyze the normalized data and detect crypto mining, we employ an enhanced semi-supervised algorithm based on the Shared Nearest Neighbour (SNN) clustering algorithm [27]. The SNN clustering defines similarity or proximity between two nodes in terms of the number of directly connected neighbors they have in common. This suits its applicability in complex networks since the clustering coefficient and vertex degrees are dictated by neighbor relations. As such, we adopt the SNN algorithm which apart from considering direct associations between nodes also considers indirect connections. This provides for an ability to detect similarities between nodes that are not necessarily adjacent. Additionally, SNN has the ability to handle clusters of varying sizes, densities and shapes. As such, two nodes that are relatively close but belong to different clusters are handled effectively.

As shown from Figure 3, our semi-supervised approach consists of two phases: 1) an unsupervised phase that produces complex network characteristics features based on vertex degrees and clustering coefficients. 2) a supervised phase that learns and trains the model. This phase uses the KNN classifier and the labeled data. In short, our semi-supervised learning approach uses the unsupervised learning method to extract features from the unlabeled dataset and the supervised model classifies this data instances of crypto mining using complex network characteristics features.

IV. Proposed Algorithms

Algorithm 1 illustrates the enhanced SNN algorithm. The unsupervised phase utilizes the shared nearest neighbor clustering whilst the supervised phase utilizes the KNN.

The semi-supervised learning approach is summarized in Algorithm 2.

The semi-supervised learning approach is summarized in Algorithm 2.
V. Results Analysis and Discussions

To apply the aforementioned framework and algorithms, we first start by analyzing the unlabeled traffic content with a protocol analyzer for crypto mining and non-crypto mining TCP and UDP traffic. The results are shown in Figure 4 below.

![Figure 4. TCP (blue) and UDP (red) traffic from the dataset](image)

We analyze traffic with crypto mining activities for the cryptocurrencies Ethereum, Monero, and Zcash for their corresponding mining pools. The diagram in Figure 5 shows traffic for the Ethereum mining pool captured via the Wireshark tool.

![Fig. 5. Traffic for the Ethereum mining pool](image)

It was noted that the mining protocols leverage TCP as the transport layer protocol. In comparison to official crypto p2p clients, the mining protocols do not necessarily use “well-known” port numbers. This is all dependent on the configuration of the administrator. As such, it is not uncommon to encounter port numbers for http=80, https/TLS=443, and SMTP=25 being of the administrator. As known port numbers. This is all dependent on the configuration of the clients, the mining protocols do not necessarily use “well-known” port numbers for crypto mining and non-mining pool server.

We use a public dataset [26] to evaluate our model. This dataset was specifically chosen because it is a publicly available repository and consists of the feature vectors and their classification (i.e., mining/non-mining) which are important because we are devising a semi-supervised approach and would not need to label the data. The feature vector specified in this dataset [26] which we later use for the supervised learning stage is outlined in Table II.

We apply different clustering algorithms in Weka [28] and later compare them with the results of SNN clustering. One of the major shortfalls of the main tool we used (Weka) is that its OutOfMemory error occurs when dealing with large datasets. One of the mitigative approaches is to strategically partition the dataset into manageable units. The table below Table III shows the results of different clustering algorithms.

<table>

Application of the SNN clustering algorithm produces 5 clusters of different properties. Table III shows 5 clusters with IDs C0, C1, C2, C3, and C4. As can be seen from Table III, the SNN algorithm performs better clustering with not only the highest numbers of clusters but even a better distribution.

Cluster C0 has a high "bytes" (97.3%) and a high "packets per minute" (79.2%). It also has a high "flags" (65.8%) compared to "Ackpush_all" (47.1%). This implies that hosts in this cluster have a higher vertex degree and clustering coefficient with regards to external communications.

On the contrary, cluster C2 has "bytes" (98.5%) and "packets per minute" (83.6%) but the "Ackpush_all" (90.6%) is greater than "flags" (75.3%). This implies that hosts in this cluster have a higher clustering coefficient and vertex degree with regards to internal communications. The number of flows with FIN flags to all flows for activities in this cluster is relatively higher than C0.

A lower "bytes" (1.6%) and a high "packets per minute" (99.6%) corresponding to "flags" (53.1%) instead of "Ackpush_all" (1.8%) for a smaller time window in cluster C4 entail that hosts in this cluster communicate more with external hosts. Furthermore, hosts in this cluster have a high "Syn_all" (97.8%) value implying a high number of synchronization connections requests to the mining pool.

</table>

The clusters C1 and C3 have relatively average network statistics that depict the behaviour of benign hosts. The high Ackpush_all (93.7%) in C1 corresponds to a high Rst_all (83.2%) which is a correlation expected of normal network traffic. Equally in cluster C3, bpp (86.1%) corresponding to ppf (86.4%) which is supplemented by average values of other characteristics in the same range. The variations in the clustering coefficient and vertex degree in these network traffic statistics in the respective clusters depict the overall movement of the movement vector from the feature centroid. The clustering results of the attributes are shown in Table IV.

After generating the clusters and associating them with crypto mining instances, we use the labeled dataset for classification and evaluate the effectiveness of our proposed approach. This is because the hosts in the labeled data are technically labeled as malicious for generating crypto mining traffic. However, we do not evaluate which stage of the crypto mining process the traffic belongs to. The detailed characteristics of the model for the hosts classified using the mining process the traffic belongs to. However, we do not evaluate which stage of the cryp technically labeled as malicious for generating crypto mining approach. This is because the hosts in the labeled data are they belong to the Miner class. If the instance highly belongs any of the classes, its threshold will be close to 1 will have orange or blue depending on the class. As such, all instances are correctly classified instances and miner instances are shown in Figure 6 and Figure 7 respectively. Each instance in the ROC curve has a threshold value of a given class (Miner or Not Miner class). If the instance highly belongs any of the classes, its threshold will be close to 1 will have orange or blue depending on the class. As such, all points above the ND line correspond to instances where the ratio of correctly classified points belonging to the Miner class is greater than the proportion of incorrectly classified points belonging to the Not Miner class. In light of this, the blue colour indicate lower thresholds whilst the orange colour indicate higher thresholds.

Correctly classified instances represent 99.72% while incorrectly classified instances represent 0.28%. The diagram in Figure 6 shows the confusion matrix of the correctly and wrongly classified instances.

![Figure 6. Confusion matrix for the model](image)

Figure 6. Confusion matrix for the model

The model has good performance because the weighted average of the ROC Area is near 1 and away above the non-discriminative characteristic (N.D) which represents equal TP and FP rates. The ROC curves for detection of not miner instances and miner instances are shown in Figure 6 and Figure 7 respectively. Each instance in the ROC curve has a threshold value of a given class (Miner or Not Miner class). If the instance highly belongs any of the classes, its threshold will be close to 1 will have orange or blue depending on the class. As such, all points above the ND line correspond to instances where the ratio of correctly classified points belonging to the Miner class is greater than the proportion of incorrectly classified points belonging to the Not Miner class. In light of this, the blue colour indicate lower thresholds whilst the orange colour indicate higher thresholds.

![Figure 7. ROC curve for the “Not Miner” class](image)

Figure 7. ROC curve for the “Not Miner” class

The ROC Area entails the predictive characteristics of the model to distinguish between the true positives and the true negatives. As such, the model does not only predict a positive value as a positive but as well as a negative value as a negative. The TP Rate represents the instances that are correctly classified as a given class which essentially is the rate of true positives. The FP Rate represents which of the instances falsely classified as a given class which essentially is the rate of false positives.

![Figure 8. ROC curve for the “Miner” class](image)

Figure 8. ROC curve for the “Miner” class

The PRC, as opposed to the ROC Area, represents the behavioral characteristics of Precision Vs Recall. The Precision value denotes the ratio of instances that are true of a given class divided by the sum of instances classified as that given class. The Recall value denotes the ratio of instances classified as a class divided by the actual sum in that given class. As such, this is equivalent to the TP rate. The F-Measure is a combined measure that depicts the ratio of double the product of Precision and Recall divided by the sum thereof, i.e. \[ \frac{2 \times \text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}} \]

The MCC is the measure of the quality of binary classifications...
taking into account true and false positives and negatives. It is a balanced measure that has a range [-1, 1], with -1 denoting a completely wrong classifier and 1 indicating the opposite. The variations in the clustering coefficient and vertex degree in these network traffic statistics in the respective clusters depict the overall movement of the movement vector from the feature centroid.

VI. Conclusions

The results presented in this paper demonstrate that the integration of semi-supervised learning with complex network theory modeling is effective at detecting crypto mining activities in a network environment. Our model’s efficiency was enhanced by first clustering unlabeled data based on dynamic complex network characteristics and classifying the resultant clusters using a proximity-based classification algorithm, hence semi-supervised learning. The dynamic network characteristics exhibited in the network traffic generated by crypto mining activities serve as the modeling basis for detection. The presence of such crypto mining traffic in a corporate network is a high indicator of compromise. Our proposed detection methodology is advantageous in that it’s independent of the nature of the victim device nor the underlying operating system since it’s solely based on dynamic network statistics. Such an approach finds wide application in heterogeneous networks with varied devices such as IoT, SCADA/ICS systems, critical infrastructure, cloud computing, and so forth.
